EM and Newton-Raphson implementation

The ABO-gene or ABO-locus is on chromosome 9. It has 3 alleles (antigens) (A, B, O) and it determines 4 blood type (A, B, AB, O).

```
AA AO A
BB BO B
AB AB
OO O

A, B are dominant to O.
```

genotype

phenotype

O is recessive to A, B.

A, B are co-dominant.

We have a large random sample obtained from Berlin (Bernstein 1925, Sham's book page 44):

- $n_A = 9123$ blood type A
- $n_B = 2987$ blood type B
- $n_{AB} = 1269$ blood type AB
- $n_O = 7725$ blood type O

For instance, $n_A = 9123 = n_{AA} + n_{AO}$: Among 9123 blood type A individuals, some have genotype AA and the others have genotype AO.

Our interest is to estimate the allele frequencies of alleles A, B, and O. i.e. p = freq (allele A), q = freq (allele B), 1 - p - q = freq (allele O).

- 1. Write out the log-likelihood L(p,q).
- 2. Is there a closed-form solution of this log-likelihood function?
- 3. Formulate the problem as a missing data problem and use the Newton-Raphson algorithm to find the MLEs, \hat{p} and \hat{q} , that maximize the log-likelihood, $\ln L(p,q)$.
- 4. (Advanced) Use the EM algorithm to find the Maximum Likelihood Estimates (MLEs) of parameters, \hat{p} and \hat{q} .

Hint: Lei Sun's STA2080 Modern genetic statistics notes (link).

Solution

1. Let $X = (n_A, n_B, n_{AB}, n_O)$, X follows the multinomial distribution,

$$L(p,q) = \left(\begin{array}{c} n \\ n_A, n_B, n_{AB}, n_O \end{array}\right) \left(p^2 + 2p(1-p-q)\right)^{n_A} \left(q^2 + 2q(1-p-q)\right)^{n_B} \left(2pq\right)^{n_{AB}} \left((1-p-q)^2\right)^{n_O}$$

The general approach to estimate allele frequency is maximum likelihood estimation. To find MLE, take the derivatives of the log-likelihood function, and find the pair of (p, q) that set the derivatives to 0.

The log transformation is performed since finding a maximizer of L(p,q) is equivalent to finding a maximizer of $\ln L(p,q)$. The log-likelihood is,

$$\ln L(p,q) \sim n_A \ln(p^2 + 2p(1-p-q)) + n_B \ln(q^2 + 2q(1-p-q)) + n_{AB} \ln(2pq) + n_O \ln((1-p-q)^2)$$
 (1)

Take the partial derivatives of the log-likelihood and set them to 0,

$$\frac{\partial \ln L(p,q)}{\partial p} = \frac{2(1-p-q)}{p(2-p-2q)} n_A + \frac{2}{2p+q-2} n_B + \frac{1}{p} n_{AB} - \frac{2}{1-p-q} n_O = 0$$
 (2)

$$\frac{\partial \ln L(p,q)}{\partial q} = \frac{2}{p+2q-2} n_A + \frac{2(1-p-q)}{q(2-2p-q)} n_B + \frac{1}{q} n_{AB} - \frac{2}{1-p-q} n_O = 0$$
 (3)

- 2. It is hard to find the explicit form of the (p,q) from equation (2) and (3) **directly**. We consider solve the problem **iteratively**.
- 3. Newton-Raphson algorithm is another method that can be applied to estimate the ABO allele frequency. The algorithm is initially designed to find the roots (or zeros) of a real-valued function iteratively.

In the ABO blood type settings, maximizing the likelihood is equivalent to finding the roots of the derivative of log-likelihood function. Since it is hard to find the roots directly, one can approximate it iteratively. Here denote the parameters to be estimated as $\vec{\theta} = (p,q)$, denote the log-like hood shown in equation (1) as $f(\vec{\theta}) = \ln L(\theta)$, then the partial derivatives of the log-likelihood (score function) is $f'(\vec{\theta}) = f'(p,q)$, the second derivatives (Hessian matrix, or observed information $-I(\theta)$) as $f''(\vec{\theta}) = f''(p,q)$. The explicit forms of the score function and observed information are shown in the appendix.

4. Expectation-Maximum (EM) algorithm is a method for obtaining the Maximum likelihood estimates (MLE) of parameters iteratively. It usually contains two parts: **E-step (expectation)** computes an expected value of the log-likelihood using current estimate for the parameters; **M-step (Maximization)** calculates MLE based on the log likelihood in the E-step, then updates the estimates of the parameters.

The EM algorithms are often used when the model contains unobserved data. In the ABO settings, one could observe the phenotype counts (n_A, n_B, n_{AB}, n_O) , while the genotype counts n_{AA} or n_{AO} in blood A group and n_{BB} or n_{BO} in blood A group and B group are missing. This leads to a problem when applying direct counting (Sham, 1998) to estimate p, q, the allele frequency of A and B respectively. The following steps will show how this missing data problem could be solved by the EM algorithm.

In each iteration k, firstly, the **E-step** computes the expected value of the log-likelihood h(p,q) using the observed data $n_{\text{obs}} = (n_A, n_B, n_{AB}, n_O)$ and current parameter value $p^{(k)}, q^{(k)}$:

$$Q_k(p,q) = E[h_k(p,q)|n_{\text{obs}}, p^{(k)}, q^{(k)}]$$
(4)

and
$$h_k(p,q) \sim 2n_{AA} \log p^{(k)} + n_{AO} \log(2p(1-p^{(k)}-q^{(k)})) + 2n_{BB} \log q^{(k)} + n_{BO} \log(2p(1-p^{(k)}-q^{(k)})) + n_{AB} \log(2p^{(k)}q^{(k)}) + 2n_O \log(1-p^{(k)}-q^{(k)})$$

Since the log-likelihood is linear w.r.t. the missing data, therefore, when taking the expectation for each component, the missing data can be imputed in this case. For example, since $E[2n_{AA}\log p^{(k)}|n_{\text{obs}},p^{(k)},q^{(k)}]=2\log p^{(k)}E[n_{AA}|n_{\text{obs}},p^{(k)},q^{(k)}]$, and under the HWE assumption,

$$E[n_{AA}|n_{\text{obs}},p^{(k)},q^{(k)}] = \frac{\operatorname{freq}(AA)}{\operatorname{freq}(AA) + \operatorname{freq}(AO)} n_A = \frac{p^{(k)}p^{(k)}}{p^{(k)}p^{(k)} + 2p^{(k)}\left(1 - p^{(k)} - q^{(k)}\right)} n_A := n_{AA}^{(k)}$$

By the similar calculation, we can get the imputed data $n_{AA}^{(k)}, n_{AO}^{(k)}, n_{BB}^{(k)}, n_{BO}^{(k)}$ for each iteration.

Then the M-step computes the MLE based on the likelihood in equation (3). To be specific,

$$\frac{\partial Q_k(p,q)}{\partial p} = \frac{2n_{AA}^{(k)} + n_{AO}^{(k)} + n_{AB}}{p} - \frac{n_{AO}^{(k)} + n_{BO}^{(k)} + n_O}{1 - p - q} = 0$$
$$\frac{\partial Q_k(p,q)}{\partial q} = \frac{2n_{BB}^{(k)} + n_{BO}^{(k)} + n_{AB}}{q} - \frac{n_{AO}^{(k)} + n_{BO}^{(k)} + n_O}{1 - p - q} = 0$$

Thus, the updated values of parameters are

$$p^{(k+1)} = \frac{2n_{AA}^{(k)} + n_{AO}^{(k)} + n_{AB}}{2n} \qquad q^{(k+1)} = \frac{2n_{BB}^{(k)} + n_{BO}^{(k)} + n_{AB}}{2n}$$
